Abstract

Data poisoning is a type of adversarial attack on machine learning models wherein the attacker adds examples to the training set to manipulate the behavior of the model at test time. This paper explores a broad class of poisoning attacks on neural nets. The proposed attacks use "clean-labels"; they don't require the attacker to have any control over the labeling of training data. They are also targeted; they control the behavior of the classifier on a *specific* test instance without noticeably degrading classifier performance on other instances.

For example, an attacker could add a seemingly innocuous image (that is properly labeled) to a training set for a face recognition engine, and control the identity of a chosen person at test time. Because the attacker does not need to control the labeling function, poisons could be entered into the training set simply by putting them online and waiting for them to be scraped by a data collection bot.

We present an optimization-based method for crafting poisons, and show that just one single poison image can control classifier behavior when transfer learning is used. For full end-to-end training, we present a "watermarking" strategy that makes poisoning reliable using multiple (≈ 50) poisoned training instances. We demonstrate our method by generating poisoned frog images from the CIFAR dataset and using them to manipulate image classifiers.

1 Introduction

Before deep learning algorithms can be deployed in high stakes, security-critical applications, their robustness against adversarial attacks must be put to the test. The existence of adversarial examples in deep neural networks (DNNs) has triggered debates on how secure these classifiers are [Szegedy et al., 2013, Goodfellow et al., 2015, Biggio et al., 2013]. Adversarial examples fall within a category of attacks called *evasion attacks*. Evasion attacks happen at test time – a clean target instance is modified to avoid detection by a classifier, or spur misclassification. However, these attacks do not map to certain realistic scenarios in which the attacker cannot control test time data. For example, consider a retailer aiming to mark a competitor's email as spam through an ML-based spam filter. Evasion attacks are not applicable because the attacker cannot modify the victim emails. Similarly,

*Authors contributed equally.

an adversary may not be able to alter the input to a face recognition engine that operates under supervised conditions, such as a staffed security desk or building entrance.

Such systems are still susceptible to *data poisoning* attacks. These attacks happen at training time; they aim to manipulate the performance of a system by inserting carefully constructed *poison instances* into the training data.

This paper studies poisoning attacks on neural nets that are *targeted*, meaning they aim to control the behavior of a classifier on one specific test instance. For example, they manipulate a face recognition engine to change the identity one specific person, or manipulate a spam filter to allow/deny a specific email of the attacker's choosing. We propose *clean label* attacks that do not require control over the labeling function; the poisoned training data appear to be labeled correctly according to an expert observer. This makes the attacks not only difficult to detect, but opens the door for attackers to succeed without any inside access to the data collection/labeling process. For example, an adversary could place poisoned images online and wait for them to be scraped by a bot that collects data from the web. The retailer described above could contribute to a spam filter dataset simply by emailing people inside an organization.

1.1 Related work

Classical poisoning attacks indiscriminately degrade test accuracy rather than targeting specific examples, making them easy to detect. While there are studies related to poisoning attacks on support vector machines [Biggio et al., 2012] or Bayesian classifiers [Nelson et al., 2008], poisoning attacks on Deep Neural Networks (*DNN*) have been rarely studied. In the few existing studies, DNNs have been shown to fail catastrophically against data poisoning attacks. Steinhardt et al. [2017] reported that, even under strong defenses, there is an 11% reduction in test accuracy when the attacker is allowed 3% training set modifications. Muñoz-González et al. [2017] propose a back-gradient based approach for generating poisons. To speed up the process of generating poisoning instances, Yang et al. [2017] develop a generator that produces poisons.

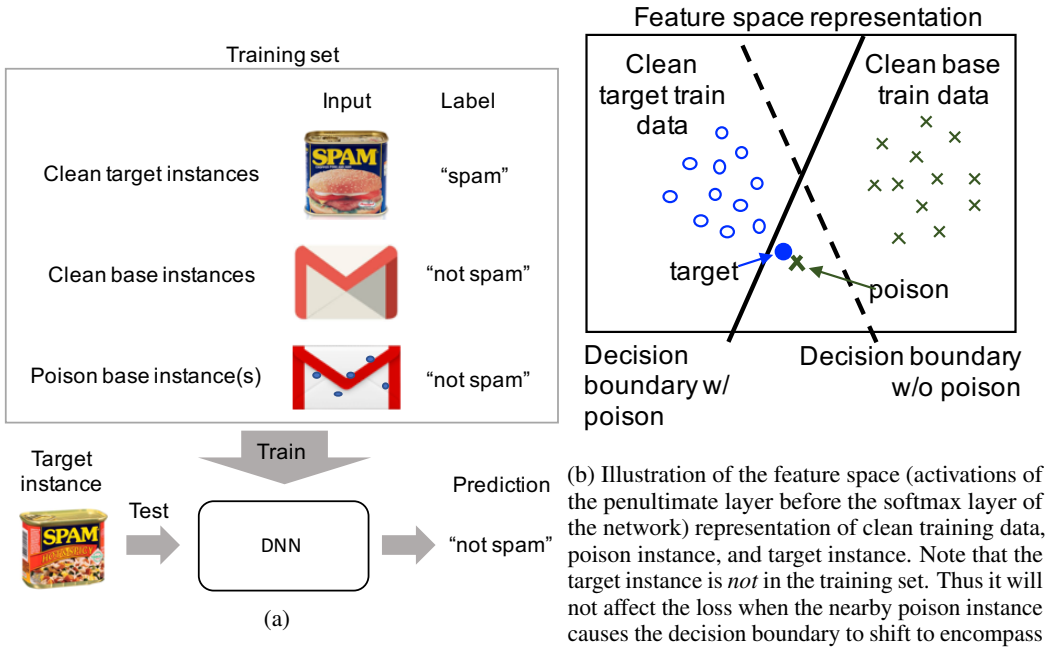
A more dangerous approach is for the attacker to target specific test instances. For example, the retailer mentioned above, besides achieving her target goal, does not want to render the spam filter useless or tip off the victim to the presence of her attack. Targeted backdoor attacks [Chen et al., 2017] with few resources ($\sim$50 training examples) have been recently shown to cause the classifier to fail for special test examples. Gu et al. [2017] trains a network using mislabeled images tagged with a special pattern, causing the classifier to learn the association between the pattern and the class label. In Liu et al. [2017] a network is trained to respond to a trojan trigger.

These attacks present the same shortcomings as evasion attacks; they require test-time instances to be modified to trigger the mispredictions. Moreover, in most prior work, the attacker is assumed to have some degree of control over the labeling process for instances in the training set. This inadvertently excludes real-world scenarios where the training set is audited by human reviewers, who will label each example as it appears to the eye, or where the labels are assigned by an external process (such as malware detectors which often collect ground truth labeled by third party antiviruses). Assumed control over the labeling function leads to a straightforward one-shot attack wherein the target instance with a flipped label is added as poison. Overfitting on the poison would then ensure that the target instance would get misclassified during inference time.

The most closely related work to our own is by Suciu et al. [2018], who study targeted attacks on neural nets. This attack requires the attacker to have complete control over the formation of training batches used during SGD, and so can only be executed by an engineer that exerts control over the entire training process.

1.2 Contributions

In this work, we study a new type of attack, henceforth called *clean-label* attacks, wherein the attacker's injected training examples are cleanly labeled by a certified authority, as opposed to maliciously labeled by the attacker herself [Chen et al., 2017]. Our strategy assumes that the attacker has no knowledge of the training data but has knowledge of the model and its parameters. This is a reasonable assumption given that many classic networks pre-trained on standard datasets, such as ResNet [He et al., 2015] or Inception [Szegedy et al., 2014] trained on ImageNet, are frequently



(b) Illustration of the feature space (activations of the penultimate layer before the softmax layer of the network) representation of clean training data, poison instance, and target instance. Note that the target instance is *not* in the training set. Thus it will not affect the loss when the nearby poison instance causes the decision boundary to shift to encompass both of them into the base region.

Figure 1: (a) Schematic of the clean-label poisoning attack. (b) Schematic of how a successful attack might work by shifting the decision boundary.

used. The attacker's goal is to cause the retrained network to misclassify a special test instance from one class (e.g. a piece of malware) as another class of her choice (e.g. benign application) after the network has been retrained on the augmented data set that includes poison instances. Besides the intended misprediction on the target, the performance degradation on the victim classifier is not noticeable. This makes state-of-the-art poisoning defenses that measure the performance impact of training instances (such as Barreno et al. [2010]) ineffective.

A similar type of attack was demonstrated using influence functions (Koh and Liang [2017]) for the scenario where only the final fully connected layer of the network was retrained on the poisoned dataset, with a success rate of 57%.

We demonstrate an optimization-based clean-label attack under the *transfer learning* scenario studied by Koh and Liang [2017], but we achieve 100% attack success rate on the same dog-vs-fish classification task. Further, we study – for the first time to our knowledge – clean-label poisoning in the *end-to-end training* scenario where all layers of the network are retrained. Through visualizations, we shed light on why this scenario is much more difficult due to the expressivity of deep networks. Informed by these visualizations, we craft a 50 poison instance attack on a deep network which achieves success rates of up to 60% in the end-to-end training scenario.

2 A simple clean-label attack

We now propose an optimization-based procedure for crafting poison instances that, when added to the training data, manipulate the test-time behavior of a classifier. Later, we'll discuss tricks to boost the power of this simple attack.

An attacker first chooses a *target instance* from the test set; a successful poisoning attack causes this target example to be misclassified during test time. Next, the attacker samples a *base instance* from the base class, and makes imperceptible changes to it to craft a *poison instance*; this poison is injected into the training data with the intent of fooling the model into labelling the target instance with the base label at test time. Finally, the model is trained on the poisoned dataset (clean dataset + poison instances). If during test time the model mistakes the target instance as being in the base class, then the poisoning attack is considered successful. Figure 1a illustrates our poisoning scheme.

2.1 Crafting poison data via feature collisions

Let $f(\mathbf{x})$ denote the function that propagates an input $\mathbf{x}$ through the network to the penultimate layer (before the softmax layer). We call the activations of this layer the *feature space* representation of the input since it encodes high-level semantic features. Due to the high complexity and nonlinearity of f, it is possible to find an example $\mathbf{x}$ that "collides" with the target in feature space, while simultaneously being close to the base instance $\mathbf{b}$ in input space by computing

$$\mathbf{p} = \underset{\mathbf{x}}{\operatorname{argmin}} \ \|f(\mathbf{x}) - f(\mathbf{t})\|_2^2 + \beta \|\mathbf{x} - \mathbf{b}\|_2^2 \tag{1}$$

The second term of Eq. 1 causes the poison instance $\mathbf{p}$ to appear like a base class instance to a human labeler (β parameterizes the degree to which this is so) and henceforth be labeled as such. Meanwhile, the first term of Eq. 1 causes the poison instance to move toward the target instance in feature space and get embedded in the target class distribution. On a clean model, this poison instance would be misclassified as a target. If the model is retrained on the clean data + poison instances, however, the linear decision boundary in feature space (Figure 1b) is expected to rotate to include the poison instance in the base class side of the decision boundary in order to avoid misclassification of that instance. Since the target instance is nearby, the decision boundary rotation may inadvertently include the target instance in the base class along with the poison instance (note that training strives for correct classification of the poison instance but not of the target instance since it is not part of the training set). This allows the unperturbed target instance, which is subsequently misclassified into the base class during test time, to gain a "backdoor" into the base class.

2.2 Optimization procedure

Our procedure for performing the optimization in Eq. 1 to obtain $\mathbf{p}$ is shown in Algorithm 1. The algorithm uses a forward-backward-splitting iterative procedure [Goldstein et al., 2014]. The first (forward) step is simply a gradient descent update to minimize the L2 distance to the target instance in feature space. The second (backward step) is a proximal update that minimizes the Frobenius distance from the base instance in input space. The coefficient β is tuned to make the poison instance look realistic in input space, enough to fool an unsuspecting human observer into thinking the attack vector image has not been tampered with.

Algorithm 1 Poisoning Example Generation

Input: target instance t, base instance b
Initialize x: $x_0 \leftarrow b$
Define: $L_p(x) = \|f(\mathbf{x}) - f(\mathbf{t})\|^2$
for $i = 1$ **to** $maxIters$ **do**
  Forward step: $\widehat{x_i} = x_{i-1} - \lambda \nabla_x L_p(x_{i-1})$
  Backward step: $x_i = (\widehat{x_i} + \lambda\beta b)/(1 + \beta\lambda)$
end for

3 Poisoning attacks on transfer learning

We begin by examining the case of transfer learning, in which a pre-trained feature extraction network is used, and only the final network (softmax) layer is trained to adapt the network to a specific task. This procedure is common in industry where we want to train a robust classifier on limited data. Poisoning attacks in this case are extremely effective. In Section 4, we generalize these attacks to the case of end-to-end training.

We perform two poisoning experiments. First, we attack a pretrained InceptionV3 [Szegedy et al., 2016] network under the scenario where the weights of all layers excluding the last are frozen. Our network and dataset (ImageNet [Russakovsky et al., 2015] dog-vs-fish) were identical to that of Koh and Liang [2017] [2]. Second, we attack an AlexNet architecture modified for the CIFAR-10 dataset by Krizhevsky and Hinton [2009] under the scenario where all layers are trained.

[2]The code is available at `https://github.com/ashafahi/inceptionv3-transferLearn-poison`

3.1 A one-shot kill attack

We now present a simple poisoning attack on transfer learned networks. In this case, a "one-shot kill" attack is possible; by adding just one poison instance to the training set (that is labeled by a reliable expert), we cause misclassification of the target with 100% success rate.

Like in Koh and Liang [2017], we essentially leverage InceptionV3 as a feature extractor and retrain its final fully-connected layer weights to classify between dogs and fish. We select 900 instances from each class in ImageNet as the training data and remove duplicates from the test data that are present in the training data as a pre-processing step[3]. After, this, we are left with 1099 test instances (698 test instances for the dog class and 401 test instances for the fish class).

We select both target and base instances from the test set and craft a poison instance using Algorithm 1 with $maxIters = 1000$. Since the images in ImageNet have different dimensions, we calculate β in Eq. 1 using

$$\beta = \beta_0 \cdot 2048^2/(dim_b)^2, \tag{2}$$

where 2048 represents the dimensionality of InceptionV3's feature space and dim_b represents the dimensionality of the base instance input image. We use $\beta_0 = 0.25$ in our experiments.

We then add the poison instance to the training data and perform cold-start training (all unfrozen weights initialized to random values). We use the Adam optimizer with learning rate of 0.01 to train the network for 100 epochs.

The experiment is performed 1099 times – each with a different test-set image as the target instance – yielding an attack success rate of 100%. For comparison, the influence function method studied in Koh and Liang [2017] reports a success rate of 57% . The median misclassification confidence was 99.6% (Fig. 2b). Further, the overall test accuracy is hardly affected by the poisoning, dropping by an average of 0.2%, with a worst-case of 0.4%, from the original 99.5% over all experiments. Some sample target instances and their corresponding poison instances are illustrated in Fig. 2a.

Note that it is not generally possible to get 100% success rate on transfer learning tasks. The reason that we are able to get such success rate using InceptionV3 on the dog-vs-fish task is because there are more trainable weights (2048) than training examples (1801). As long as the data matrix is full-rank (no duplicates), the system of equations that needs to be solved to find the weight vector is under-determined and as a consequence has multiple solutions: overfitting on all of the training data is certain to occur.

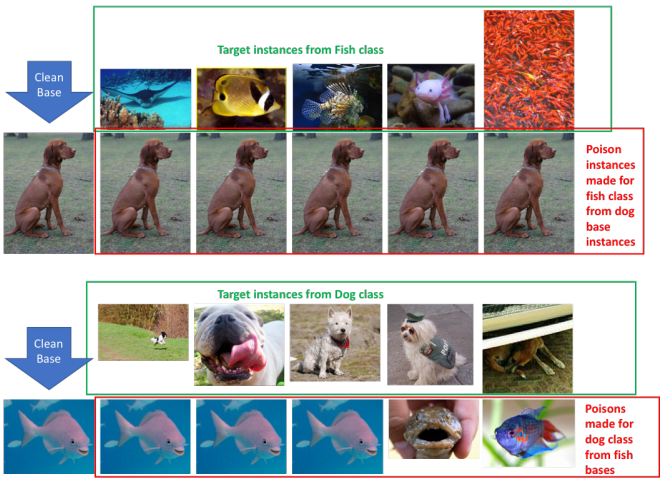
To better understand what causes the attacks to be successful, we plot the angular deviation between the decision boundary (i.e. the angular difference between the weight vectors) of the clean and poisoned networks in Fig. 3 (blue bars and lines). The angular deviation is the degree to which retraining on the poison instance caused the decision boundary to rotate to encompass the poison instance within the base region. This deviation occurs mostly in the first epoch as seen in Fig. 3b, suggesting that the attack will succeed even under suboptimal retraining hyperparameters when given more epochs. The final deviation of 23 degrees on average (Fig. 3a) indicates that a substantial alteration to the final layer decision boundary is made by the poison instance. These results verify our intuition that misclassification of the target occurs due to changes in the decision boundary.

Below we present an attack that is effective when all layers of a neural net are retrained. In this "end-to-end" training scenario (red bars and lines in Fig. 3a), the decision boundary is stationary, implying a different mechanism by which the successful poisoning occurs. We discuss this scenario in the next section.

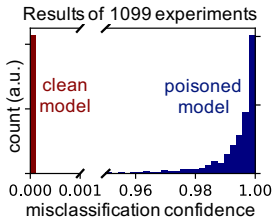
4 Poisoning attacks on end-to-end training

We saw in Section 3 that poisoning attacks are simple and extremely effective when the feature extraction layers of a network are not retrained. When all layers are trainable, these attack become

[3]If an identical image appears in both the train and test set, it could be chosen as both a base and target, in which case poisoning is trivial. We remove duplicate images to prevent this sort of "cheating."

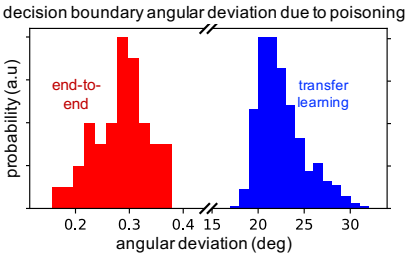


(a) Sample target and poison instances.

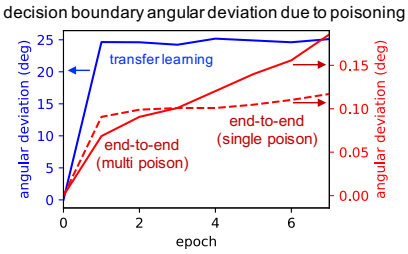


(b) Incorrect class's probability histogram predicted for the target image by the clean (dark red) and poisoned (dark blue) models. When trained on a poisoned dataset, the target instances not only get misclassified; they get misclassified with high confidence.

Figure 2: Transfer learning poisoning attack. (a) The top row contains 5 random target instances (from the "fish" class). The second row contains the constructed poison instance corresponding to each of these targets. We used the same base instance (second row, leftmost image) for building each poison instance. The attack is effective for any base, but fewer iterations are required if the base image has a higher resolution. We stopped the poison generation algorithm when the maximum iterations was met or when the feature representation of the target and poison instances were less than 3 units apart (in Euclidean norm). The stopping threshold of 3 was determined by the minimum distance between all pairs of training points. As can be seen, the poison instances are visually indistinguishable from the base instance (and one another). Rows 3 and 4 show samples from similar experiments where the target (fish) and base (dog) classes were swapped.



(a) PDF of decision boundary angular deviation.



(b) Average angular deviation vs epoch.

Figure 3: Angular deviation of the feature space decision boundary when trained with clean dataset + poison instance(s) versus when trained with clean dataset alone. (a) Histogram of the final (last epoch) angular deviation over all experiments. In transfer learning (blue), there is a significant rotation (average of 23 degrees) in the feature space decision boundary. In contrast, in end-to-end training (red) where we inject 50 poison instances, the decision boundary's rotation is negligible. (b) Most of the parameter adjustment is done during the first epoch. For the end-to-end training experiments, the decision boundary barely changes.

more difficult. However using a "watermarking" trick and multiple poison instances, we can still effectively poison end-to-end networks.

Our end-to-end experiments focus on a smaller network and dataset[4]. We train a scaled-down AlexNet architecture for the CIFAR-10 dataset (architectural details in appendix), initialized with pretrained weights (warm-start), and optimized with Adam at learning rate of 1.85×10^{-5} over 10 epochs and batch size of 128. Because of the warm-start, the loss was constant over the last few epochs after the network had readjusted to correctly classify the poison instances. We verified that enough training had been executed by certifying that the poison instances are correctly classified with high confidence.

4.1 Single poison instance attack

We start by studying an illustrative example of attacking a network with a single poison instance. Our goal is to visualize the effect of a poison on the network's behavior, and explain why poisoning attacks under the end-to-end training scenario are much more difficult than under the transfer learning scenario. For the experiments, we randomly selected "airplane" as the target class and "frog" as the base class. For crafting poison instances, we used a β value of 0.1 and iteration count ($maxIters$) of 12000.

Figure 4a shows the target, base, and poison feature space representations visualized by projecting the 193-dimensional deep feature vectors onto a 2-dimensional plane. The first dimension is along the vector joining the centroids of the base and target classes ($\mathbf{u} = \mu_{base} - \mu_{target}$), while the second dimension is along the vector orthogonal to $\mathbf{u}$ and in the plane spanned by $\mathbf{u}$ and θ (the weight vector of the penultimate layer, i.e. the normal of the decision boundary). This projection allows us to visualize the data distribution from a viewpoint best representing the separation of the two classes (target and base).

We then evaluate our poisoning attack by training the model with the clean data + single poison instance. Fig. 4a shows the feature space representations of the target, base, and poison instances along with the training data under a clean (unfilled markers) and poisoned (filled markers) model. In their clean model feature space representations, the target and poison instances are overlapped, indicating that our poison-crafting optimization procedure (Algorithm 1) works.

Oddly, unlike the transfer learning scenario where the final layer decision boundary rotates to accommodate the poison instance within the base region, the decision boundary in the end-to-end training scenario is *unchanged* after retraining on the poisoned dataset, as seen in Fig. 3.

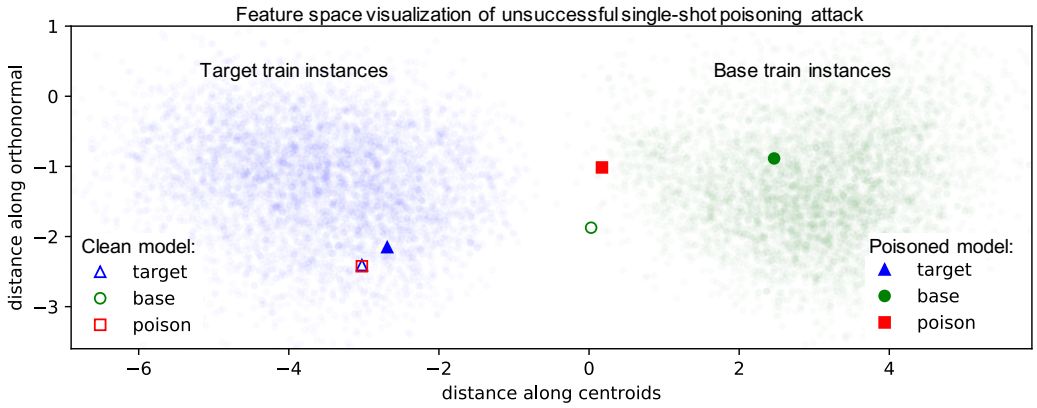
From this, we make the following important observation: *During retraining with the poison data, the network modifies its lower-level feature extraction kernels in the shallow layers so the poison instance is returned to the base class distribution in the deep layers.*

In other words, the poison instance generation exploits imperfections in the feature extraction kernels in earlier layers such that the poison instance is placed alongside the target in feature space. When the network is retrained on this poison instance–because it is labeled as a base–those early-layer feature kernel imperfections are corrected and the poison instance is returned to the base class distribution. This result shows that the objectives of poison instance generation and of network training are mutually opposed and thus a single poison may not be enough for compromising even extreme outlier target examples. To make the attacks successful, we must find a way to ensure that the target and poison instances do not get separated in feature space upon retraining.

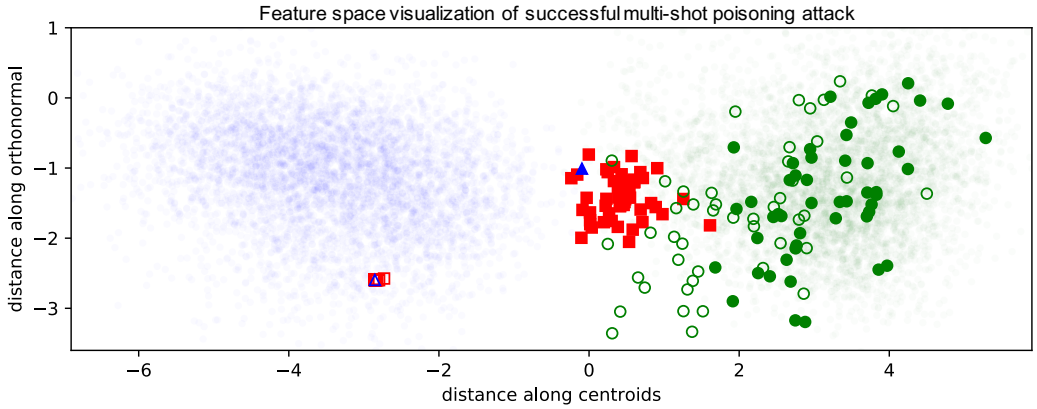
4.2 Watermarking: a method to boost the power of poison attacks

To prevent the separation of poison and target during training, we use a simple but effective trick: add a low-opacity watermark of the target instance to the poisoning instance to allow for some inseparable feature overlap while remaining visually indistinct. This blends some features of the target instance into the poison instance and should cause the poison instance to remain within feature space proximity of the target instance even after retraining. Watermarking has been previously used

[4]We do this to keep runtimes short since quantifying performance of these attacks requires running each experiment (and retraining the whole network) hundreds of times.



(a)



(b)

Figure 4: Feature space visualization of end-to-end training poisoning attacks. (a) A single poison instance is unable to successfully attack the classifier. The poison instance's feature space position under the clean model is overlapped with that of the target instance. However, when the model is trained on the clean + poisoned data (i.e. the poisoned model), the feature space position of the poison instance is returned to the base class distribution, while target remains in the target class distribution. (b) To make the attack successful, we construct 50 poison instances from 50 random base instances that are "watermarked" with a 30% opacity target instance. This causes the target instance to be pulled out of the target class distribution (in feature space) into the base class distribution and get incorrectly classified as the base class.

in Chen et al. [2017], but their work required the watermark to be applied during inference time, which is unrealistic in situations where the attacker cannot control the target instance.

A watermarked image with a target opacity of γ is formed as

$$\mathbf{b} \leftarrow \gamma \cdot \mathbf{t} + (1 - \gamma) \cdot \mathbf{b}. \tag{3}$$

Some randomly selected poison instances are shown in the appendix. Watermarks are not visually noticeable even up to 30% opacity for some target instances. Fig. 5 illustrates 60 poison instances used for successfully attacking a "bird" target instance.

4.2.1 Multiple poison instance attacks

Poisoning in the end-to-end training scenario is difficult because the network learns feature embeddings that optimally distinguish the target from the poison. But what if we introduce multiple poison instances derived from different base instances into the training set?

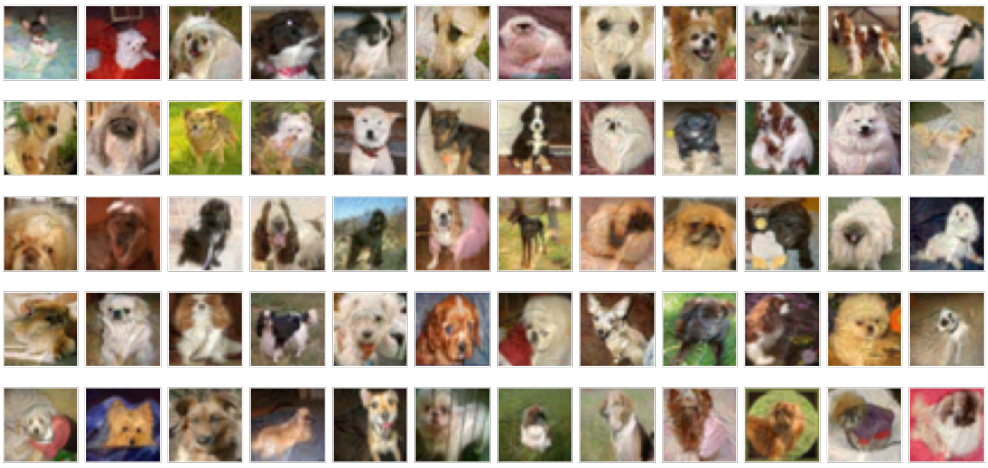


Figure 5: 60 poison instances that successfully cause a target instance belonging to the bird class to get misclassified as a dog in the end-to-end training scenario. An adversarial watermark (opacity 30%) of the target bird instance has been applied to the base instances used for making the poisons. More examples are in the appendix.

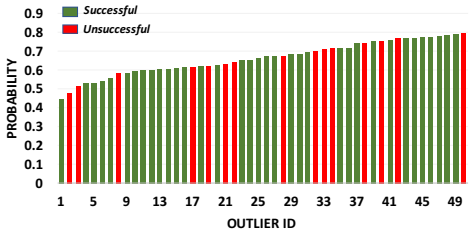
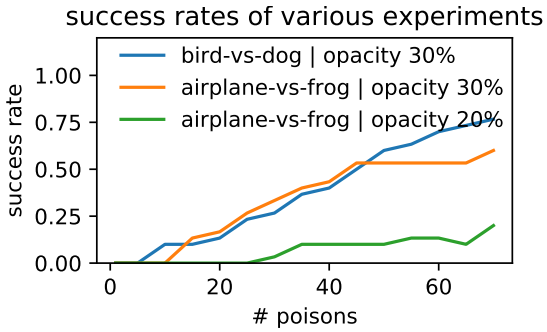


(a) Experiments on the most outlier targets. The bars indicate the probability of the target instance before the attack (calculated using the pre-trained network). Targets are ordered by outlier ID (1st/greatest outlier has the lowest probability). Green/red bar coloring denotes whether the attack was successful/unsuccessful on the corresponding target. Each experiment utilizes a watermark opacity of 30% and 50 poisons. Out of these 50 outliers, the attack succeeds 70% of the time (compare to 53% for a random target).



(b) Success rate of attacks on different targets from different bases as a function of number of poison instances used and different target opacity added to the base instances.

Figure 6: Success rates for attacks on outliers and random targets. While attacking non-outlier is still possible, attacking an outlier can increase the chances of success.

For the classifier to resist multiple poisons, it must learn a feature embedding that separates *all* poison instances from the target while also ensuring that the target instance remains in the target distribution. We show in our experiments that using a high diversity of bases prevents the moderately-sized network from learning features of the target that are distinct from those of the bases. Consequently, when the network is retrained, the target instance is pulled along with the poison instances toward the base distribution, and attacks are frequently successful. These dynamics are shown in Fig. 4b.

In Fig. 3, we observe that even in the multiple poison experiments, the decision boundary of the final layer remains unchanged, suggesting that there's a fundamentally different mechanism by which poisoning succeeds in the transfer learning vs. end-to-end training scenarios. Transfer learning reacts to poisons by rotating the decision boundary to encompass the target, while end-to-end training reacts by pulling the target into the base distribution (in feature space).

Unlike the transfer learning scenario where misclassification of the target instance is due to changes in the decision boundary, the decision boundary in the end-to-end scenario remains stationary (varying by fractions of a degree) under retraining on the poisoned dataset, as shown in Fig. 3.

To quantify how the number of poison instances impacts success rate, we ran experiments for each number of poison instances between 1 and 70 (increments of 5). Each experiment used a randomly chosen target instance from the test set. Each poison instance was generated from a random base in the test set (resulting in large feature diversity among poisons). A watermarking opacity of 30% or 20% was also used to enhance feature overlap between the poison and target instances. The attack success rate (over 30 random trials) is shown in Fig. 6b. The set of 30 experiments was repeated for a different target-base class pair within CIFAR-10 to verify that the success rates are not class dependent. We also try a lower opacity and observe that the success rate drops. The success rate increases monotonically with the number of poison instances. At 50 poisons, for instance, the success rate is about 60% for the bird-vs-dog task. Note we constrain our definition of success to the number of target instances classified as a base; the attack is considered unsuccessful even when the target instance is misclassified to a class other than the base.

We can increase the success rate of this attack by targeting data outliers. These targets lie far from other training samples in their class, and so it should be easier to flip their class label. We target the 50 "airplanes" with the lowest classification confidence (but still correctly classified), and attack them using 50 poison frogs per attack. The success rate for this attack is 70% (Fig. 6a), which is 17% higher than for randomly chosen targets.

To summarize, clean-label attacks under the end-to-end scenario require multiple techniques to work: (1) optimization via Algorithm 1, (2) diversity of poison instances, and (3) watermarking [5].

4.3 Ablation study: How many frogs does it take to poison a network?

We perform a leave-one-out ablation study to show the effect of each of the poisoning methods described above. Feature representations for attacking a particular target instance (before and after adversarial training) are visualized in Fig. 7. Results are shown for a process using all of the methods described above (row a), which produces a successful attack.

Row (b) shows a process that only uses one base to produce all the poisons. Training with multiple adversarial instances from the same base is called "adversarial training," and makes the network robust against adversarial examples [Goodfellow et al., 2015]. For this reason, reusing the base image causes poisoning to fail. Row (c) shows a process that excludes optimization to produce feature collisions, and (d) shows a process that leaves out watermarking.

5 Conclusion

We studied targeted clean-label poisoning methods that attack a net at training time with the goal of manipulating test-time behavior. Unlike other poisoning attacks, these attacks are difficult to detect because they involve non-suspicious (correctly labeled) training data, and do not degrade the performance of the classifier on non-targeted examples.

The proposed attack crafts poison images that collide with a target image in feature space, thus making it difficult for a network to discern between the two. These attacks are extremely powerful in the transfer learning scenario, and can be made powerful in more general contexts by using multiple poison images and a watermarking trick.

Note that our training with poison instances is akin to the *adversarial training* technique used as a defense to evasion attacks (Goodfellow et al. [2015]). The poison instance can here be seen as an adversarial example to the base class. While our poisoned dataset training does indeed make the network more robust to base-class adversarial examples designed to be misclassified as the target, it also has the effect of causing the unaltered target instance to be misclassified as a base. This side effect of adversarial training was exploited in this paper, and is worth further investigation.

Many neural networks are trained using data sources that are easily manipulated by adversaries (such as images/text/code scraped from the web). While successful poisoning attacks are more difficult to

A Comparison to adversarial examples

The clean-label targeted poison attack is similar to adversarial examples in the sense that they both are used for misclassifying a particular target instance. However, they differ in the kinds of freedom the attacker has on manipulating the target. Adversarial examples assume that the target can be slightly modified and hence they craft an example which looks very similar to the target instance in input space but gets misclassified. In the targeted clean-label framework, we assume that the attacker has no control over the target instance during test time and can not (or is not willing to) modify it even slightly. This makes the threat posed more concerning, as it allows one to control the classifier's decisions on test-time instances outside their spectrum of control. This framework could be also useful for fooling a face recognition system. While it has been shown that an adversary can craft accessories for a target such that wearing that accessory causes the face-recognition system to misclassify the target Sharif et al. [2016], Chen et al. [2017], there are many sensitive situations which the target is prevented from wearing any accessories.

B Sampling the candidate target instance for more success

As mentioned in the main body, a smart attacker will maximize her chances of success by choosing an effective and easy to manipulate target instance. Because outliers are separated from most training samples, the decision boundary can easily change in this location without substantially affecting classification accuracy. Also, points chosen near the decision boundary require less manipulation of the classifier in order to change its behavior. Note that the 2D illustration in Figure 1b belies the relative ease with which this condition can be fulfilled in higher dimensional spaces; nonetheless, this condition provides a heuristic by which we chose our target instances when we want higher success rates (Fig. 6a).

C Network architecture for CIFAR-10 classifier

The scaled down AlexNet architecture attacked during the end-to-end experiments is summarized in Table 1. Without poisoning, the network has a training accuracy of 100% and a test accuracy of 74.5%. To reach this accuracy, the network is trained for 200 epochs on clean data (non-poisoned) with a learning rate that decays with a schedule. The final learning rate is the one used for retraining the model once the training data set is poisoned.

Table 1: Network architecture for the poisoning of CIFAR-10 experiments.

	Type	Kernel Size	#Out Dim.
1	Conv+ReLU	5×5	64
2	MaxPool $1/2$	3×3	64
3	LRN	-	64
4	Conv+ReLU	5×5	64
5	MaxPool $1/2$	3×3	64
6	LRN	-	64
7	FullyConnected+ReLU	-	384
8	FullyConnected+ReLU	-	192
9	FullyConnected	-	10

D What do watermarked poisons look like?

The poison instances' appearance depends on the target instance being attacked and also the level of transparency (opacity) of the target instance being added to the base instances for making poison instances (Fig. 8). Attacking target instances from the birds class using poison instances built from base instances belonging to the dog class (Fig. 10) are both more successful and the poison instance images look less disturbed than the airplane-vs-frog attack (Fig. 9). If the auditor does not know the target instance (similar to the situation in Fig. 5) and is not seeing all of the poison instances side-by-side, the chances that the poison instances would be flagged as threats should not be very high.

When multiple objects are present in am image, they could be exploited to craft an attack. For example, many images of the ImageNet data set contain multiple objects from different classes, although the image has only one label. A clever watermarking for these situations could add the target instance or parts of the target instance with a higher opacity in a place where it seems innocuous. For example, one can add the airplane target instance flying in the background of a poisoned frog instance. Or if the task is to misclassify Bob as Alice, the attacker can add images of Bob to group photos in which Alice is present.

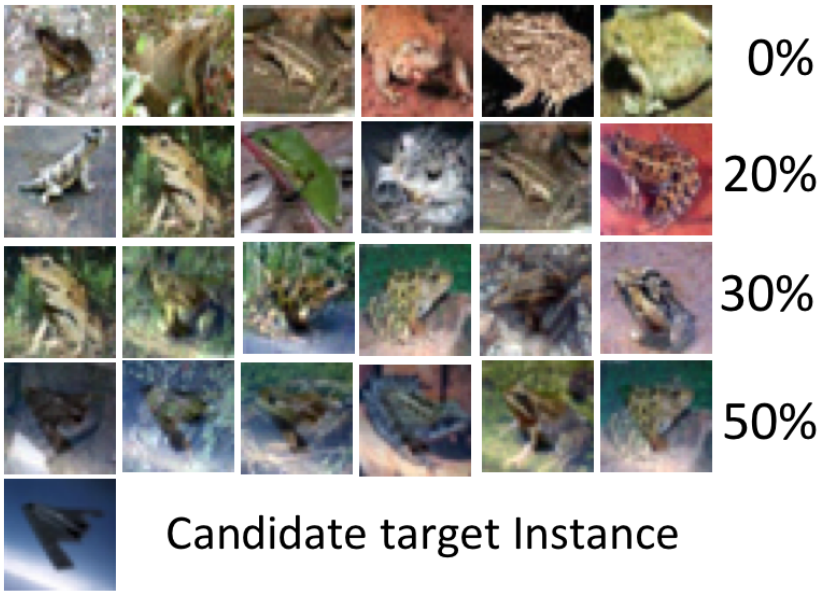

Figure 8: Poison frogs. Every row contains optimized poisoning instances built from random images belonging to the base class (frog) for the given candidate target instance that belongs to the airplane class. We apply an adversarial watermark (a transparent overlay of the target instance "airplane" image) with different opacity levels. These poisoning instances are close to the airplane in feature space. For CIFAR-10 images, 30% opacity watermarks are often hard to recognize and an unassuming human labeler would almost certainly properly label these images as "frog." However, for opacity 50% the watermark is noticeable.

Figure 9: Some samples of poisons made for different plane targets using base instances as frogs. Note that, the bases were watermarked with a 30% opacity of the target. The target instance is on the top row and some of the poisons are below it. A green dot is used when the attack was successful and red dots indicate unsuccessful attacks. Note that the images do not always look clean compared to the bird vs dog task presented in Fig. 10. But it is important to note that when the target is not known, it may be hard to recognize it's existence in all images.

Figure 10: Some sample target and poison instances for the task of attacking a target instance from the bird class using base instances from the dog class. The columns with the green dot above them are successful attacks. Similar, to the other experiment (attack), a 30% opacity of the target is added to the base instance. Note that the poison instances here are better looking than the poison instances of the plane-frog task. Also, the attacks are more successful for this task. To verify that this attack is hardly detectable to an non-suspicious label auditor, one should only look at one column and ignore the top row because the auditor/labeler is not aware of the target.
